## **1 DESCRIPTION**

### **1.1 Purpose**

Data collected, analyzed and described here as used to inform the site design activities for NEON project Teams, EHS (permitting), FCC, ENG and FSU. This document presents all the supporting data for FIU site characterization.

### **1.2 Scope**

This document presents the FIU site characterization data are for the three D10 shortgrass steppe tower locations, CPER Pawnee site (Core), North Sterling site (Relocatable 1), and RMNP CastNet site (Relocatable 2).

### 2.3 Verb Convention

"Shall" is used whenever a specification expresses a provision that is binding. The verbs "should" and "may" express non-mandatory provisions. "Will" is used to express a declaration of purpose on the part of the design activity.

### 3 CENTRAL PLAINS EXPERIMENTAL RANGE (PAWNEE GRASSLANDS), ADVANCED TOWER

#### 3.1 Site description

The Central Plains Experimental Range (CPER) is located at the western edge of the Pawnee National Grasslands in Colorado, and administered by the USDA-Agricultural Research Service. The CPER is 19 km northeast of Nunn, Colorado. The CPER includes 6300 hectares of undulating rangeland at an elevation of 1500-1700 m (Hanson et al., 1996). The NEON tower location and measurement area are at this open field and relatively flat grassland.

Average annual precipitation averages 212 mm and ranges between 101 and 508 mm. Approximately 80% of the precipitation occurs between April and September (Hanson et al., 1996). The region is composed of shale and interbedded sandstones from the Laramie formation with extensive alluvial and eolian reworking of soils (Kelly et al., 1993). Currently, grazing by domestic livestock is the primary land use of native grassland, which occupies about 60% of the land area of the shortgrass steppe.

##### 3.1.1 Ecosystem

The biotic communities of the shortgrass steppe ecosystem are particularly well-adapted for drought, with vegetative species such as blue grama (*Bouteloua gracilis*) and prickly-pear cactus (*Opuntia polyacantha*), large herbivores such as cattle (and previously, bison), and burrowing animals such as the black-tailed prairie dog (*Cynomys ludovicianus*) playing dominant roles in ecosystem function and maintenance.

The main natural plant communities are shortgrass steppe, floodplain shrubland, and salt meadow. The ecosystem is dominated by short grasses (64%), succulents (21%) and dwarf shrubs (8%). Blue grama predominates and contributes 60 to 80% percent of plant cover, biomass, and net primary productivity. Long-lived C4 grasses such as blue grama dominate under the characteristically dry conditions of the shortgrass steppe by efficiently accessing available water. Other important plants include buffalo grass (*Buchloe dactyloides*), prickly pear cactus, rabbitbrush (*Chrysothamnus nauseosa*) and saltbush (*Atriplex canescens*). The shortgrass steppe stores most biomass and resources belowground, so that aboveground disturbances do not drastically alter the vegetative community (information source: [http://sgs.cnr.colostate.edu/about\\_location.aspx](http://sgs.cnr.colostate.edu/about_location.aspx)). Mean canopy height is ~0.4 m. The surface roughness and zero place displacement height are estimated to be ~0.06 m (0.15 canopy height, Arya, 1988, p. 150) and ~0.26 m (0.7 canopy height, Arya 1988 page 151), respectively.

Pronghorn (*Antilocapra americana*) are among the most common wildlife species seen on shortgrass steppe. Black-tailed prairie dogs (*Cynomys ludovicianus*), through their clipping and burrowing activities, are also conspicuous, and create habitat for a number of other invertebrate and vertebrate animals, including horned larks (*Eremophila alpestris*), mountain plovers (*Charadrius montanus*), and burrowing owls (*Athene cunicularia*). Other species of special conservation interest or concern include the swift fox (*Vulpes velox*) and the lark bunting (*Calamospiza melanocorys*), the state bird of Colorado (information source: [http://sgs.cnr.colostate.edu/about\\_location.aspx](http://sgs.cnr.colostate.edu/about_location.aspx)).

### 3.2 Soils

Soil data and soil maps (Figure 1 and 2) below for CPRE Pawnee site were collected from 1 km<sup>2</sup> and 50 m<sup>2</sup> NRCS soil maps, which centered at the tower location, to determine the dominant soil types in the larger tower foot print. This was done to assure that the soil array is in the dominant (or in the co-dominant) soil type present in the tower footprint.

**Figure 1.** 1 km<sup>2</sup> soil map for CPRE Pawnee site, center at tower location.

**Figure 2.** 50 m2 soil map for CPRE Pawnee site, center at tower location.

**Map Unit Description** The map units delineated on the detailed soil maps in a soil survey represent the soils or miscellaneous areas in the survey area. The map unit descriptions in this report, along with the maps, can be used to determine the composition and properties of a unit. A map unit delineation on a soil map represents an area dominated by one or more major kinds of soil or miscellaneous areas. A map unit is identified and named according to the taxonomic classification of the dominant soils. Within a taxonomic class there are precisely defined limits for the properties of the soils. On the landscape, however, the soils are natural phenomena, and they have the characteristic variability of all natural phenomena. Thus, the range of some observed properties may extend beyond the limits defined for a taxonomic class. Areas of soils of a single taxonomic class rarely, if ever, can be mapped without including areas of other taxonomic classes. Consequently, every map unit is made up of the soils or miscellaneous areas for which it is named and some minor components that belong to taxonomic classes other than those of the major soils. Most minor soils have properties similar to those of the dominant soil or soils in the map unit, and thus they do not affect use and management. These are called non-contrasting, or similar, components. They may or may not be mentioned in a particular map unit description. Other minor components, however, have properties and behavioral characteristics divergent enough to affect use or to require different management. These are called contrasting, or dissimilar, components. They generally are in small areas and could not be mapped separately because of the scale used. Some small areas of strongly contrasting soils or miscellaneous areas are identified by a special symbol on the maps. If included in the database for a given area, the contrasting minor components are identified in the map unit descriptions along with some characteristics of each. A few areas of minor components may not have been observed, and consequently they are not mentioned in the descriptions, especially where the pattern was so complex that it was impractical to make enough observations to identify all the soils and miscellaneous areas on the landscape. The presence of minor components in a map unit in no way diminishes the usefulness or accuracy of the data. The objective of mapping is not to delineate pure taxonomic classes but rather to separate the landscape into landforms

| NEON Doc. #: NEON.DOC.011026                          |                      | Revision: D      |

or landform segments that have similar use and management requirements. The delineation of such segments on the map provides sufficient information for the development of resource plans. If intensive use of small areas is planned, however, onsite investigation is needed to define and locate the soils and miscellaneous areas. An identifying symbol precedes the map unit name in the map unit descriptions. Each description includes general facts about the unit and gives important soil properties and qualities. Soils that have profiles that are almost alike make up a soil series. All the soils of a series have major horizons that are similar in composition, thickness, and arrangement. Soils of a given series can differ in texture of the surface layer, slope, stoniness, salinity, degree of erosion, and other characteristics that affect their use. On the basis of such differences, a soil series is divided into soil phases. Most of the areas shown on the detailed soil maps are phases of soil series. The name of a soil phase commonly indicates a feature that affects use or management. For example, Alpha silt loam, 0 to 2 percent slopes, is a phase of the Alpha series. Some map units are made up of two or more major soils or miscellaneous areas. These map units are complexes, associations, or undifferentiated groups. A complex consists of two or more soils or miscellaneous areas in such an intricate pattern or in such small areas that they cannot be shown separately on the maps. The pattern and proportion of the soils or miscellaneous areas are somewhat similar in all areas. Alpha-Beta complex, 0 to 6 percent slopes, is an example. An association is made up of two or more geographically associated soils or miscellaneous areas that are shown as one unit on the maps. Because of present or anticipated uses of the map units in the survey area, it was not considered practical or necessary to map the soils or miscellaneous areas separately. The pattern and relative proportion of the soils or miscellaneous areas are somewhat similar. Alpha-Beta association, 0 to 2 percent slopes, is an example. An undifferentiated group is made up of two or more soils or miscellaneous areas that could be mapped individually but are mapped as one unit because similar interpretations can be made for use and management. The pattern and proportion of the soils or miscellaneous areas in a mapped area are not uniform. An area can be made up of only one of the major soils or miscellaneous areas, or it can be made up of all of them. Alpha and Beta soils, 0 to 2 percent slopes, is an example. Some surveys include miscellaneous areas. Such areas have little or no soil material and support little or no vegetation. Rock outcrop is an example. Additional information about the map units described in this report is available in other soil reports, which give properties of the soils and the limitations, capabilities, and potentials for many uses. Also, the narratives that accompany the soil reports define some of the properties included in the map unit descriptions.

### 3.2.1 Soil semi-variogram description

The goal of this site characterization of soil using semi-variograms is to determine the minimum distance between the soil plots in the soil array that can be considered spatially independent. The spatial variation of surface soil will be estimated using field sampling data of soil temperature and soil water content (SWC) in the tower airshed at Central Plains Experimental Range (CPER) Pawnee site.

The collected soil temperature and SWC data at field will be used for semi-variograms, which is a geostatistical technique to detect spatial autocorrelation between mapped samples of a quantitative variable (e.g. temperature and SWC in our case). In a variogram, the averaged squared difference in the residual value of a variable between all pairs of points is computed across distance intervals (lag classes). The output is presented graphically as a plot of the average semi-variance versus distance class (Figure 3). The semi-variance will converge on total variance at distances for which values are no longer spatially auto-correlated (this is referred to as the range, Figure 3).

Three parameters estimated from the variogram describe spatial autocorrelation in the data (Figure 3): the range, the sill (the sill is the asymptotic value of semi-variance at the range), and the nugget variance (which describes sampling error or variation at distances below those separating the closest pairs of samples). The range, sill and nugget variance were estimated from theoretical models that were fitted to the empirical variograms using non-linear least squares methods. The range distance (i.e. the distance beyond which samples are spatially independent) was estimated from the empirical variogram by fitting

spherical theoretical models. This is the distance we will use to determine the spatial separation of soil plots in soil array.

The variogram analysis will be used in turn, to determine the spatial scales at which we can consider soil measurements spatially independent. This characterization will directly inform the minimal distance between *i*) soil plot within each soil array, *ii*) the soil profile measurements, *iii*) EP plots, and *iv*) the microbial sampling. These data will directly inform NEON construction and site design activities.

Figure 3. Example semivariogram, depicting range, sill, and nugget.

**3.2.2 Soil Semi-Variogram Method, Experimental design, data analysis**

Field measurements of soil temperature and soil water content (SWC) were taken on August 13 and August 14, 2009 at the Central Plains Experimental Range (CPER) Pawnee site following the spatially cyclic sampling design by Bond-Lamberty et al. (2006, Figure 4). This design uses repeated pattern of samples to provide information about all distance with minimum of redundancy.

Figure 4. Spatially cyclic sampling design for the measurements of soil temperature and soil water content.

|   |                      |                  |
|---|----------------------|------------------|
| Title: D10 FIU Site Characterization: supporting data | Author: Loescher/Luo | Date: 05/15/2013 |
| NEON Doc. #: NEON.DOC.011026                          |                      | Revision: D      |

One 210-meter and two 84-meter transects were established at CPER Pawnee grasslands site. All transect were centered at the same location (Latitude: N40.81722, Longitude: W104.74924). First transect was 210 meters and ran toward the direction of 340° (compass magnetic degrees, same below) from the pre-designed tower location (Latitude: N40.81636, Longitude: W104.74901). Sampling points for this transect were 26. Second transect was 84 meters and ran NE-SW direction (40°-220°) with 11 sampling points. Third transect was 84 meters and ran SE-NW direction (100°– 280°) with 11 sampling points. A Garmin GPS device was used to record the sampling location. All transects were set in the expected airshed (dominant wind directions, Figure 5, Figure 6). Rough airshed area was determined by the wind roses that were established based on the historic wind direction and wind speed data. The determination of accurate airshed area by models will be described in the “Airshed” session below.

**Figure 5.** Established transects at Pawnee Grassland site

These transects were used for field measurements of soil temperature and soil water content for site characterization of soil. Tower location presented was the pre-designed tower location.

**Figure 6.** Established transects at CPRE Pawnee advance tower site.

3 replicates (30 cm apart from one another, Figure 7) were measured at each sampling point at fixed-depth (0-20 cm) using platinum resistance temperature sensors (RTD 810, Omega Engineering Inc., Stamford CT) for soil temperature and time domain dielectric sensors (CS616, Campbell Scientific Inc., Logan UT) for SWC at each sampling points. Data collected were used for geospatial analyses of variograms in the R statistical computing language with the geoR package to test for spatial autocorrelation (Goovaerts, 1997; Trangmar et al., 1985; Webster, 1989) and to determine the distance for soil plots in the soil array.

For all data sets for temperature and SWC, there is evidence for the existence of spatial trends that can be modeled as a function of time. This is a consequence of the fluctuating solar radiation throughout the day. Trends were estimated and removed with a simple two parameter linear regression model and p-values for the model significance are provided in the respective text below in results session. For the most part, this approach was sufficient with respect to satisfying the assumption of stationarity. Hence, variogram models were constructed on the residuals from these regressions of the response variable on time. The range distance (*i.e.*, the distance beyond which samples are spatially independent) was estimated from the empirical variogram by fitting spherical theoretical models to both soil temperature and SWC data.

**Figure 7.** Three replicates of soil temperature and SWC

Measurements at each sampling point were at fixed-depth (0-20 cm). These 3 replicates are 30 cm apart from one another along the established transects at the CPRE Pawnee advance tower site.

### 3.2.3 Results and interpretation

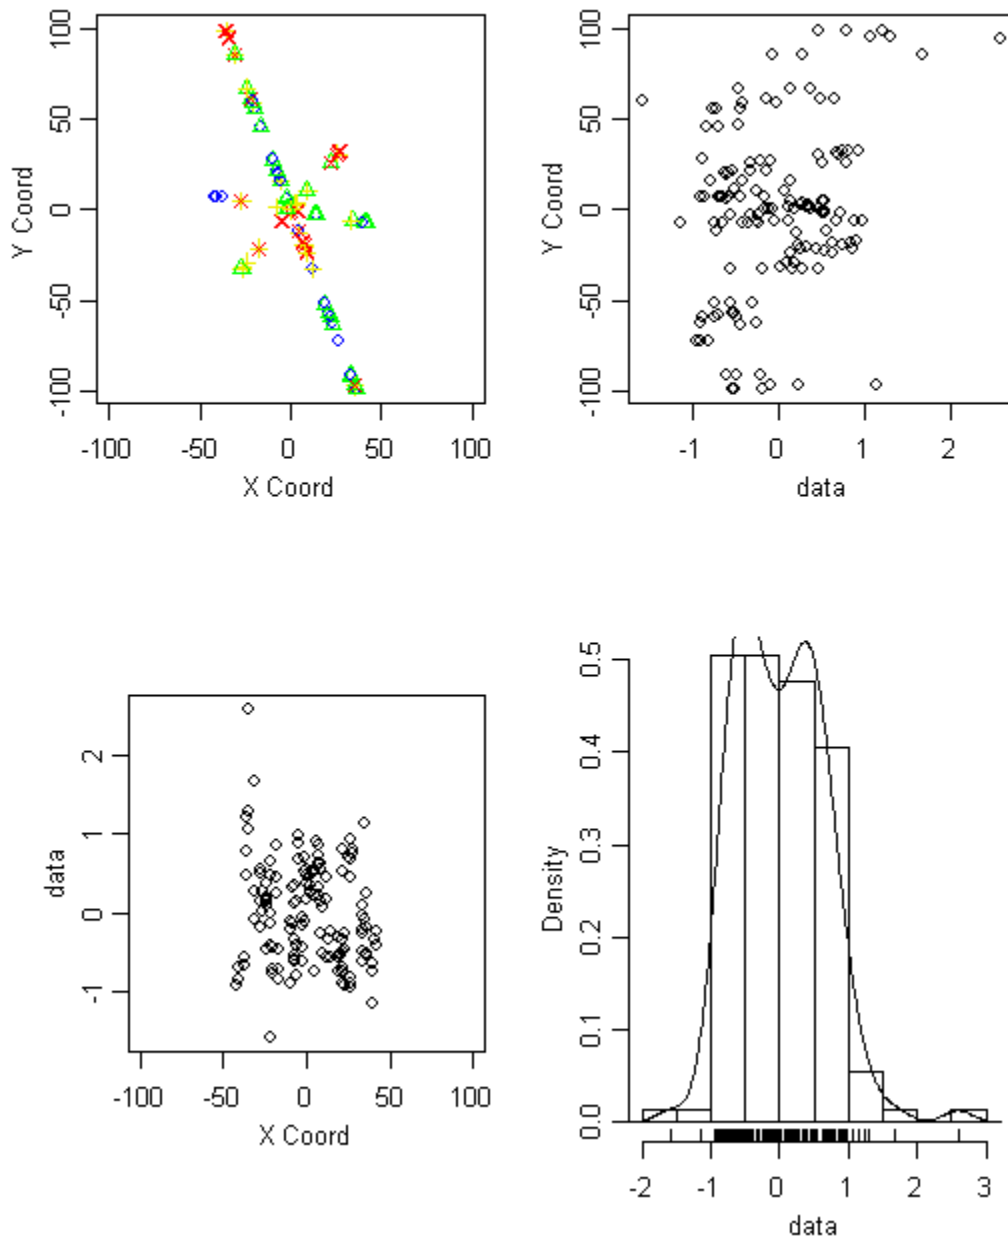

#### **Temperature**

The temperature data display a strong pattern as a function of time. A linear regression ( $p < 0.001$ ) of temperature on time was fit and used to extract this trend (Figure 8). Exploratory data analysis plots show that there is no distinct patterning of the residuals (Figure 9). Directional variograms of the residuals do not show any indication of anisotropy (Figure 10). It is worth noting here that the sampling design allowed for a better characterization of the directional variograms relative to the sampling design at Sterling. A spherical covariance model was fit using Cressie weights and a maximum distance of 125 meters (Figure 11). The estimated distance of effective independence was 88 meters. This information will be used to refine the design applied to the subsequent sites. If the maximum distance between samples in the final sampling design is less than the distance of effective independence, then increased sampling density may be required to achieve a nominal sample size in the presence of correlated data.

**Figure 10.** Directional variograms for residuals from regression of temperature on time at the CPRE Pawnee advance tower site.

**Figure 11.** Empirical variogram and model fit for the residuals of the regression of temperature on time at the CPRE Pawnee advance tower site.

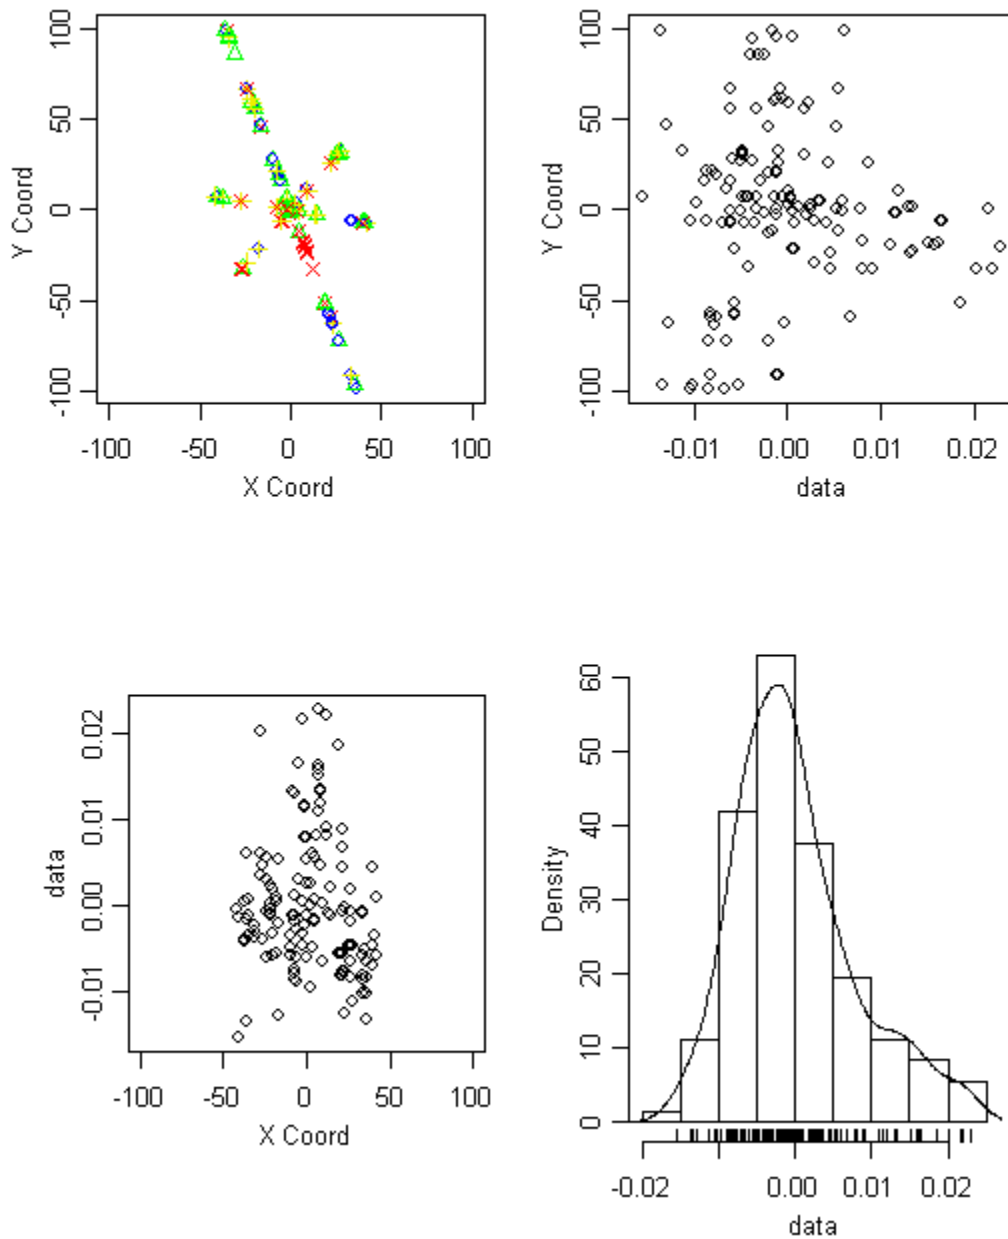

### Soil Water Content

The soil water content (SWC) data display a decreasing pattern as a function of time. A linear regression ( $p < 0.001$ ) of temperature on time was fit and used to extract this trend (Figure 12). Exploratory data analysis plots show that there is an increase in the spread of the residuals with respect to the center of the y-axis (upper right corner Figure 13). Directional variograms of the residuals do not show any indication of anisotropy (Figure 14). A spherical covariance model was fit using Cressie weights (Figure 15) and the estimated distance of effective independence was 35 meters. This information is used to refine the design applied to the subsequent sites.

### 3.2.4 Summary

The estimated distance of effective independence was 88 meters based on geospatial analysis of temperature data alone, which is impossible to separate soil plots so far apart due to the practical economic reasons. The estimated distance of effective independence was found to be 35 meters with a well-defined sill based on the geospatial analysis on SWC. This is confirmed by a previous study (Hanson et al., 1996) on spatial analysis of other soil properties (bulk density, percentage sand, percentage clay, percentage CaCO<sub>3</sub> and percentage organic matter, etc.) at the same location of Pawnee grassland. The majority of the range results for above soil property variables are <35 meters in this study. Therefore, we are confident that the soil plots 35 meters apart from one another will be adequate to avoid the autocorrelation.

## 3.3 Airshed

### 3.3.1 Seasonal windroses

Wind roses analytically determine and graphically represent the frequencies of wind direction and wind speed over a given timeseries (Figure 16 – 19). The orientation of the wind rose follows that of a compass. When we describe the wind directions it should be noted that they are the cardinal direction that wind blows from. Color bands depict the range of wind speeds. The directions of the rose with the longest spoke show wind directions with the largest frequency. These wind roses are subdivided into as 16 cardinal directions.

Data used here are hourly data from 1986 to 2007. Data was collected and obtained from the datasets of Short Grass Steppes Long Term Ecological Research (SGS-LTER) site, and compiled by B. McNoldy. Data were collected by a propeller anemometer mounted at 2.2 m inside the Agricultural Research Service (ARS) experimental area surrounded by flat topography. It is assumed that the wind data was corrected for declination.

### 3.3.2 Resultant vectors

**Table 2.** The resultant wind vectors from CPER Pawnee site using hourly data from 1999 to 2009.

| Quarterly (seasonal) timeperiod | Resultant vector | % duration |

### 3.3.3 Acceptance criteria (overview)

Micrometeorological theory and the eddy covariance technique were established over uniform vegetative canopies with short roughness lengths on flat terrain and large fetch. The objective is to place a tower in such a way to optimize the amount of time where all the flows (winds) and microclimate with minimal disturbance and secondary filtering. Flow through the tower must be discounted and screened against data quality criteria. Flows that pass through a tower often have to be screened and filtered out of a long-term dataset. Part of the task here is to position the tower to optimize the amount of time wind flows from the desired landscape. Here at Pawnee, the tower was moved toward the south and east within the property boundary – to optimize the temporal coverage of desired flows, and to minimize the influence of the neighboring (undesirable) land use types. Additional concerns and acceptance criteria can be found in the FIU Tower Science requirements (AD[01]).

The tower should be sited to maximize the time with winds blowing from the desired land cover type, and with the longest upwind fetch attainable. If the surroundings are not of a uniform cover type, there needs to be some analysis of prevailing winds to demonstrate that the desired sectors are sampled uniformly through time. Consider the extreme example of a site with two different forest types and a consistent daily wind cycle that blew from one forest type and in the day and the other at night. Daily integrated NEE in this situation would be un-interpretable. This extreme condition is unlikely, but many sites could have more subtle wind direction biases that need to be examined and considered in data interpretation. All systems are subject to horizontal flux divergence, advective motions, wake effects and drainage of air sheds (AD[01]). Footprint analyses to determine the source area under different stabilities, wind speeds and direction among seasons provide valuable guidance for appropriate tower placement, documentation of site characteristics, and definition of data acceptance criteria (Foken & Leclerc, 2004; Horst & Weil, 1992; Horst & Weil, 1994a; Horst & Weil, 1994b; Horst, 2001; Kormann & Meixner, 2001; Schmid & Lloyd, 1999; Schmid, 1994; Schuepp et al., 1990). The criteria for tower placement should not only be concerned with the summer, productive periods, but also the seasonal transitional periods (spring and fall), and winter months when respiration process often dominate.

Micro-topography requires visual inspection. Long wave forms and standing waves are commonplace over short stature ecosystems, where the topographic relief is < 10 m, and with high (mechanical turbulent) winds. Preliminary data collection may be useful to determine if micro-topographic features affect the local microclimate and flow regimes.

|   |                      |                  |
|---|----------------------|------------------|
| Title: D10 FIU Site Characterization: supporting data | Author: Loescher/Luo | Date: 05/15/2013 |
| NEON Doc. #: NEON.DOC.011026                          |                      | Revision: D      |

The tower needs to be high enough to place the sensors well above the surrounding canopy, but not so high that the footprint during stable night-time conditions extends beyond the boundary of the ecosystem type of interest.

Other constraints are placed on our ability to locate and position a tower besides available footprint and flow regimes. At some locations, there is a large sensitivity towards viewing the tower above the canopy from houses, scenic over views, or within an urban area. This public concern is particularly prevalent in State and National Parks. A second constraint is the amount of land available for construction. Lastly, there are often nearby land uses or ecosystem types that can contribute undesirable information (fluxes, meteorology) to the tower based measurements. For example, different grazing patterns in a nearby field, large wetlands in the center of the desired footprint, roads that cause line sources of dust or hydrocarbons, or clearcuts that generate conflicting non-local circulations (Loescher et al., 2004). All these issues have to be balanced to achieve the scientific requirements.

Windroses were constructed on a seasonal basis where, i) the first estimation is the maximum and average seasonal windspeeds, ii) the season fractional wind directions, and iii) is the resultant wind direction.

Winds at CPER Pawnee site are dominant from the north quadrant (Table 2), and annual resultant wind vector is from 348°. However, winds do come from the other quadrants during the summer months, due to the convective scales and storm fronts (Figure 18). Convective fronts develop daytime winds along the front range and generally pass over the site, travelling from the west to the east. But as they pass over they re-direct the winds to other vectors, from the east, south etc. (Figure 18).

The desired measurements are from lightly grazed, natural and minimally managed shortgrass prairie, with the dominant soil association being Ascalon fine silt loam with 0-6° slope (48% spatially dominant). The available west-to-east length of this ecosystem is ~800 m. Immediately to the east is another managed block of shortgrass prairie, but is managed as over grazed. These eastern winds would have to be inspected for data quality, and would be potentially biased by the differences in management and the subsequent changes in microclimate and biochemical cycling (flux rates). Hence, flows from the east are least desirable. Because flows through the tower have to be examined and potentially removed from the dataset, placing the leeward side of the tower closest to the east, optimizes flows over the source area from the west. To maximize the fetch (source area) from the NW from the winter, spring and fall seasons, the tower location should be placed in the SE area of the parcel. Because winds from the south occur during the summer and the results from the footprint analyses (Figures 20 - 23) indicate 80% of the cumulative flux is derived over ~ 200-300 m under summer convective conditions, the tower placement should be ~ 300 m north of the southern boundary. Instrument hut shall be placed in the leeward side of the tower and not influence the flows around the tower, hence, the distance of ~ 5 x the hut height towards the east of the tower is required (AD[02]).

**3.3.5 Expected environmental controls on source area**

Two types of models were used to determine the shape and extent of the source area under different and contrasting atmospheric stability classes. An inverted plume dispersion model with modeled cross wind solutions were used for convective conditions (Horst & Weil, 1994). For strongly stable conditions, and Lagrangian solution was used (Kormann & Meixner, 2001). Here, the source area models were bounded by the expected conditions depicting the extreme conditions. Convective conditions typically have strong vertical mixing between the ecosystem and atmosphere (surface layer). Stable conditions typically winds have longer wave forms, that integrate measurements over 1000's m. Convective turbulence is often characterized by short mixing scales (scalar) and moderate daytime

|---|-----------------------|------------------|
| Title: D10 FIU Site Characterization: supporting data | Author: Loeschler/Luo | Date: 05/15/2013 |
| NEON Doc. #: NEON.DOC.011026                          |                       | Revision: D      |

windspeeds, *e.g.*, 1-4 m s<sup>-2</sup>. Higher windspeeds, like those experienced over the Rockies, are often the product of mechanical turbulence with long waveforms. Because thermal stratification is very efficient in suppressing vertical mixing, stable conditions also have typically very long waveforms.

As a general rule, shorter and less structurally complex ecosystems (Pawnee and North Sterling) have good vertical mixing during all atmospheric stabilities. Taller and more structurally complex ecosystems have well mixed upper canopies during the daytime, and can be decoupled below the canopy under neutral and stable conditions. The type of turbulence (mechanical versus convective) and the physical attributes of the ecosystem controls the degree of mixing, and the length and size of the source area.

Winds used for these model results are founded on the wind roses (Figure 16-19). Run 1 represents the expected conditions for near-neutral atmospheres, run 2 for stable atmospheres, and runs 3 and 4 for convective conditions. The primary difference between runs 3 and 4 is the maximum and average expected winds used, respectively. The annual resultant wind vector is placed as a centerline in the site map included in the graphics. The crosswind component: the width of the footprint was also estimated using the length of the 80% cumulative flux to calculate the angle from centerline, Appendix A. Figure A1.

**Figure 23. Tower flux footprint output for CPER Pawnee site under convective conditions at maximum expected wind speed using an inverted plume dispersion model by Horst & Well.**

Because the ecosystem has a height of the mean plant canopy < 1.75 m, the Tower has been sited to i) the minimize the remove foliage during the tower establishment, ii) optimize the temporal coverage of flow-based measurements over the representative environment, iii) minimize flow distortions caused by local ecosystem structure or topography (orography), and iv) allow the sensors on the tower booms to measure the representative surrounding environment. The location identified here and its final placement (e.g., construction activities, FCC micrositing) will have to be evaluated against these conditions and requirements.

To avoid edge effect on science measurements, tower, soil array, and sensor locations have been sited such that the meteorological sensors and soil sensors are  $\geq 60$  m away from the edge of the representative ecosystem in interest, and flux sensors are  $\geq 180$  m from the edge of the representative ecosystem. The sensor locations identified here and its (final) placement (e.g., during reviews, construction activities, FCC micrositing) will have to be evaluated against these conditions and requirements.

DFIR location at this site has been chosen to meet USCRN class 1 or class 2 criteria. The DFIR location identified here and its (final) placement (e.g., during reviews, construction activities, FCC micrositing) will have to be evaluated against these conditions and requirements.

### 3.3.7 Constraints on the FSU ecosystem plot locations

Winds are dominant from the north quadrant (Table 2), and annual resultant wind vector is from 348°. However, winds do come from the other quadrants during the summer months, due to the convective scales and storm fronts. The ecosystem productivity plots should be placed within i) the overall, annual extent of the footprint, ii) within the bounds of the permitted property, iii) span the dominant and co-dominant soil types, and iv) estimate the productivity from the ecosystem if interest. Given these constraint and the location of the tower, the shape of the overall, annual source is a large fan (where the apex is the tower location). The northern vector is  $325^\circ + 27^\circ = 353^\circ$  (constrained by the resultant angle and footprint angle). The length of the northern vector is 400 m. The southern vector is  $135^\circ$  constrained by windrose and property boundary. The length of the southern vector is  $\sim 300$  m.

### 3.4 Exclusion Zone

To meet our Product Assurance metrics, our high quality Terrestrial Instrument System (TIS) measurements, and TIS requirements, no sampling, observations, or experiment shall be conducted within the tower exclusion zone without consulting and resolving any issues with TIS scientists as according to the 'NEON Research Collaboration Document' NEON.DOC.004312. The intent is to limit any activities that can either affect the wind flows (e.g., disturbance, buildings, structures, clear cutting, affect changes in structure), or the natural/expected process rates. Because we cannot think of all such future activities, each will have to be evaluated on a case-by-case basis.

The exclusion zone is an area with these features:

- a) The shape of the exclusion zone appears as a pie splice (plan view) with center point of the tower foundation (plan view) as its origin.
- b) There may be more than one exclusion zone per tower, depending on the diurnal, seasonal and annual wind patterns.
- c) The exclusion zone is a sub-area (i.e., inside) the total tower source area
- d) Windrose analyses determine the wind vectors that bound the outside of the exclusion zone, which is clockwise from 163 to 15 degrees at this site (major).

There are two criteria to determine the distance of the exclusion zone from the tower:

- 1) For all activities mentioned above, the distance from the tower is the maximum value of 90% cumulative flux of the source area at mean maximum wind speed under daytime convective (expected unstable) atmospheres, which is 600 m at this site.
- 2) Some large disturbance activities also cannot occur in the nighttime tower footprint (because the nighttime tower footprint extends out much farther than the daytime source area). For all high impact activities, the distance from the tower is the maximum value of 80% cumulative flux of the source area at mean maximum wind speed under nighttime, thermally stratified, (expected) stable atmospheric conditions, which is 400 m at this site.

## 4 NORTH STERLING, RELOCATEABLE TOWER 1

### 4.1 Site description

The North Sterling relocatable tower site (Latitude: N 40°27'53.05", Longitude: W 103°01'46.49") is located near Sterling, CO at a elevation ~1350 m and is about 500 m on the south-west of the junction of the County Road 59 and County Road 6. It is at the edge of a non-tilled experimental field that is used for the long-term sustainable Dryland Agroecosystems Project (DAP), which was initiated in 1985 at three sites in eastern Colorado (Sterling, Stratton, and Walsh) to evaluate the effects of cropping intensity on production, water use efficiency, and selected soil chemical and physical properties (Peterson et al., 1993). Summers are hot and low humid, winters are typically around freezing point, but can drop lower temperature. Occasional hail storms and thunderstorms are expected during the growing seasons. Seasonal high wind and tornados shall be considered in the tower design.

**History:** The site was established in 1985 and was chosen because of the three representative soils present in the catena. Prior to establishment of the no-till cropping systems the site had been under conventional tillage since it was taken from native sod in about 1910. Conventional tillage from 1910 to 1985 ranged from moldboard plowing in the early years to sweep tillage in the later years. The primary crop was winter wheat grown in a wheat-fallow rotation. Proso millet also had been grown occasionally in a few years prior to 1985.

Cropping systems under no-till management were initiated in 1985. These systems included: winter wheat (*Triticum aestivum* L.)-fallow (WF); winter wheat-maize (*Zea mays* L.)-fallow (WMF); winter wheat-maize-proso millet (*Panicum miliaceum* L.)-fallow (WMPF); continuous cropping (CC) (crops grown over the years included maize, sorghum, winter wheat, forage millet, and sunflower); and perennial grass (G). The systems represent a gradient of cropping intensity (crops divided by years in the rotation), Thus WF has an intensity factor of 0.50. Intensity factors for WMF, WMPF, and CC are 0.67, 0.75, and 1.0, respectively. The Native grass treatment does not have an intensity factor since it is a perennial system. Grass stands were established in the spring of 1986 and contain a mixture of perennial species including both warm and cool season grasses.

The long-term average annual precipitation and temperature values are ~440 mm and ~9.5 °C for this site. Long-term cropping season open pan evaporation averages 1600 mm and the evapotranspiration (ET) is relatively low at this site (Table 5, Andales et al., 2003). The crop rotations were wheat-corn-millet-fallow at this experimental site. Crops were planted using no-till planters and drills that only disturbed the soil in a narrow band to allow for a seed row. The candidate tower location is at the edge of this non-tilled experimental field (east) and a tilled private farmland (west), which is under conventional tillage crop-fallow management for at least 70 years (Ascough II et al., 2007). Because of the prevailing wind is from west direction, although the NEON tower location is inside the non-tilled experimental farmland, the major measurement areas (tower source area) will fall in the tilled private agricultural farmland.

The summit loam soil at Sterling is relatively shallow, with a partially cemented layer at about 90-cm depth that is slowly permeable to water but relatively impermeable to roots. The summit soil profile at this site had a root restriction at 90-cm depth (Andales et al., 2003). The soil physical and hydraulic properties are presented in Table 2 (Ascough II et al., 2007).

**Table 5.** General site information at the North Sterling relocatable tower site

| NEON Doc. #: NEON.DOC.011026                          |                      | Revision: D      |

**4.1.1 Ecosystem**

The crop rotations here are wheat-corn-millet-fallow at the non-tilled experiments site on the east of the tower. However, the crop rotations in the tilled private farmland are unknown, which is mainly driven by the market needs, price and agricultural policies. Therefore, canopy height can vary from 0 meter for fallow to 3-4 m for the mature corn stands. The roughness length also varies from 0.05 m to ~0.2 m, and zero plane displacement varies from 0 m to 2-3 m.

**4.2 Soils**

Soil data and soil maps (Figure 24 and 25) below for North Sterling Relocatable site were collected from 1 km<sup>2</sup> and 50 m<sup>2</sup> NRCS soil maps, which centered at the tower location, to determine the dominant soil types in the larger tower foot print. This was done to assure that the soil array is in the dominant (or in the co-dominant) soil type present in the tower footprint.

**Figure 24.** 1km<sup>2</sup> soil map for North Sterling Relocatable site, center at tower location.

#### 4.2.1 Description of soils

**Map Unit Description.** The map units delineated on the detailed soil maps in a soil survey represent the soils or miscellaneous areas in the survey area. The map unit descriptions in this report, along with the maps, can be used to determine the composition and properties of a unit. A map unit delineation on a soil map represents an area dominated by one or more major kinds of soil or miscellaneous areas. A map unit is identified and named according to the taxonomic classification of the dominant soils. Within a taxonomic class there are precisely defined limits for the properties of the soils. On the landscape, however, the soils are natural phenomena, and they have the characteristic variability of all natural phenomena. Thus, the range of some observed properties may extend beyond the limits defined for a taxonomic class. Areas of soils of a single taxonomic class rarely, if ever, can be mapped without including areas of other taxonomic classes. Consequently, every map unit is made up of the soils or miscellaneous areas for which it is named and some minor components that belong to taxonomic classes other than those of the major soils. Most minor soils have properties similar to those of the dominant soil or soils in the map unit, and thus they do not affect use and management. These are called non-contrasting, or similar, components. They may or may not be mentioned in a particular map unit description. Other minor components, however, have properties and behavioral characteristics divergent enough to affect use or to require different management. These are called contrasting, or dissimilar, components. They generally are in small areas and could not be mapped separately because of the scale used. Some small areas of strongly contrasting soils or miscellaneous areas are identified by a special symbol on the maps. If included in the database for a given area, the contrasting minor

|   |                      |                  |
|---|----------------------|------------------|
| Title: D10 FIU Site Characterization: supporting data | Author: Loescher/Luo | Date: 05/15/2013 |
| NEON Doc. #: NEON.DOC.011026                          |                      | Revision: D      |

components are identified in the map unit descriptions along with some characteristics of each. A few areas of minor components may not have been observed, and consequently they are not mentioned in the descriptions, especially where the pattern was so complex that it was impractical to make enough observations to identify all the soils and miscellaneous areas on the landscape. The presence of minor components in a map unit in no way diminishes the usefulness or accuracy of the data. The objective of mapping is not to delineate pure taxonomic classes but rather to separate the landscape into landforms or landform segments that have similar use and management requirements. The delineation of such segments on the map provides sufficient information for the development of resource plans. If intensive use of small areas is planned, however, onsite investigation is needed to define and locate the soils and miscellaneous areas. An identifying symbol precedes the map unit name in the map unit descriptions. Each description includes general facts about the unit and gives important soil properties and qualities. Map Unit Description: Weld loam, 1 to 3 percent slopes—Logan County, Colorado Sterling\_1KM Natural Resources Conservation Service Web Soil Survey National Cooperative Soil Survey 7/22/2009

Soils that have profiles that are almost alike make up a soil series. All the soils of a series have major horizons that are similar in composition, thickness, and arrangement. Soils of a given series can differ in texture of the surface layer, slope, stoniness, salinity, degree of erosion, and other characteristics that affect their use. On the basis of such differences, a soil series is divided into soil phases. Most of the areas shown on the detailed soil maps are phases of soil series. The name of a soil phase commonly indicates a feature that affects use or management. For example, Alpha silt loam, 0 to 2 percent slopes, is a phase of the Alpha series. Some map units are made up of two or more major soils or miscellaneous areas. These map units are complexes, associations, or undifferentiated groups. A complex consists of two or more soils or miscellaneous areas in such an intricate pattern or in such small areas that they cannot be shown separately on the maps. The pattern and proportion of the soils or miscellaneous areas are somewhat similar in all areas. Alpha-Beta complex, 0 to 6 percent slopes, is an example. An association is made up of two or more geographically associated soils or miscellaneous areas that are shown as one unit on the maps. Because of present or anticipated uses of the map units in the survey area, it was not considered practical or necessary to map the soils or miscellaneous areas separately. The pattern and relative proportion of the soils or miscellaneous areas are somewhat similar. Alpha-Beta association, 0 to 2 percent slopes, is an example. An undifferentiated group is made up of two or more soils or miscellaneous areas that could be mapped individually but are mapped as one unit because similar interpretations can be made for use and management. The pattern and proportion of the soils or miscellaneous areas in a mapped area are not uniform. An area can be made up of only one of the major soils or miscellaneous areas, or it can be made up of all of them. Alpha and Beta soils, 0 to 2 percent slopes, is an example. Some surveys include miscellaneous areas. Such areas have little or no soil material and support little or no vegetation. Rock outcrop is an example. Additional information about the map units described in this report is available in other soil reports, which give properties of the soils and the limitations, capabilities, and potentials for many uses. Also, the narratives that accompany the soil reports define some of the properties included in the map unit descriptions.

#### 4.2.2 Soil Semi-variograms

The goal of this site characterization of soil using semi-variograms is to determine the minimum distance between the soil plots in the soil array that can be considered spatially independent. The spatial variation of surface soil will be estimated using field sampling data of soil temperature and soil water content (SWC) in the tower airshed at the North Sterling Relocatable site.

The field collected soil temperature and SWC data will be used for semi-variograms, which is a geostatistical technique to detect spatial autocorrelation between mapped samples of a quantitative variable (e.g. temperature and SWC in our case). In a variogram, the averaged squared difference in the residual value of a variable between all pairs of points is computed across distance intervals (lag classes). The output is presented graphically as a plot of the average semi-variance versus distance class (Figure 3). The semi-variance will converge on total variance at distances for which values are no longer spatially auto-correlated (this is referred to as the range, Figure 3).

Three parameters estimated from the variogram describe spatial autocorrelation in the data (Figure 1): the range, the sill (the sill is the asymptotic value of semi-variance at the range), and the nugget variance (which describes sampling error or variation at distances below those separating the closest pairs of

| Title: D10 FIU Site Characterization: supporting data | Author: Loescher/Luo | Date: 05/15/2013 |
| NEON Doc. #: NEON.DOC.011026                          |                      | Revision: D      |

samples). The range, sill and nugget variance were estimated from theoretical models that were fitted to the empirical variograms using non-linear least squares methods. The range distance (i.e. the distance beyond which samples are spatially independent) was estimated from the empirical variogram by fitting spherical theoretical models. This is the distance we will use to determine the spatial separation of soil plots in soil array.

The variogram analysis will be used in turn, to determine the spatial scales at which we can consider soil measurements spatially independent. This characterization will directly inform the minimal distance between *i*) soil plot within each soil array, *ii*) the soil profile measurements, *iii*) EP plots, and *iv*) the microbial sampling. These data will directly inform NEON construction and site design activities.

#### 4.2.3 Soil Semi-Variogram Method, experimental design, data analysis

Measurements of soil temperature and soil water content (SWC) were taken on August 10, 2009 at the North Sterling Relocatable site following the spatially cyclic sampling design by Bond-Lamberty *et al.* (2006, Figure 4). This design uses repeated pattern of samples to provide information about all distance with minimum of redundancy.

Two 210-meter transects were established at North Sterling Relocatable tower site. Both started from a location (Latitude: N40.46198°Longitude: W103.02941°) that next to the tower location (Figure 26). All transects were set in the expected airshed (dominant wind directions, Figure 26). Rough airshed area was determined by the wind roses that were established based on the historic wind direction and wind speed data. The determination of accurate airshed area by models will be described in the “Airshed” section below.

First transect was 210 meters and ran toward the West direction of 270° (compass magnetic degrees, same below) from the potential tower location. Second transect was 210 meters and ran toward SW direction (220°). Each transects has 26 sampling points. A Garmin GPS device was used to record the sampling location. 3 replicates (30 cm apart from one another, Figure 27) were measured at each sampling point along established transects using platinum resistance temperature sensors (RTD810, Omega Engineering Inc.) for soil temperature and time domain dielectric sensors (CS616, Campbell Scientific, Inc.) for SWC at each sampling points.

Soil temperature and SWC data collected were used for geospatial analyses of variograms in the R statistical computing language with the geoR package to test for spatial autocorrelation (Goovaerts, 1997; Trangmar *et al.*, 1985; Webster, 1989) and to determine the distance for soil plots in the soil array.

For all data sets for temperature and SWC, there is evidence for the existence of spatial trends that can be modeled as a function of time. This is a consequence of the fluctuating solar radiation throughout the day. Trends were estimated and removed with a simple two parameter linear regression model and p-values for the model significance are provided in the respective text below in results session. For the most part, this approach was sufficient with respect to satisfying the assumption of stationarity. Hence, variogram models were constructed on the residuals from these regressions of the response variable on time. The range distance (i.e. the distance beyond which samples are spatially independent) was

The device on his back includes a datalogger, 3 soil temperature sensors, and 3 soil water content sensors used for site characterization of soil.

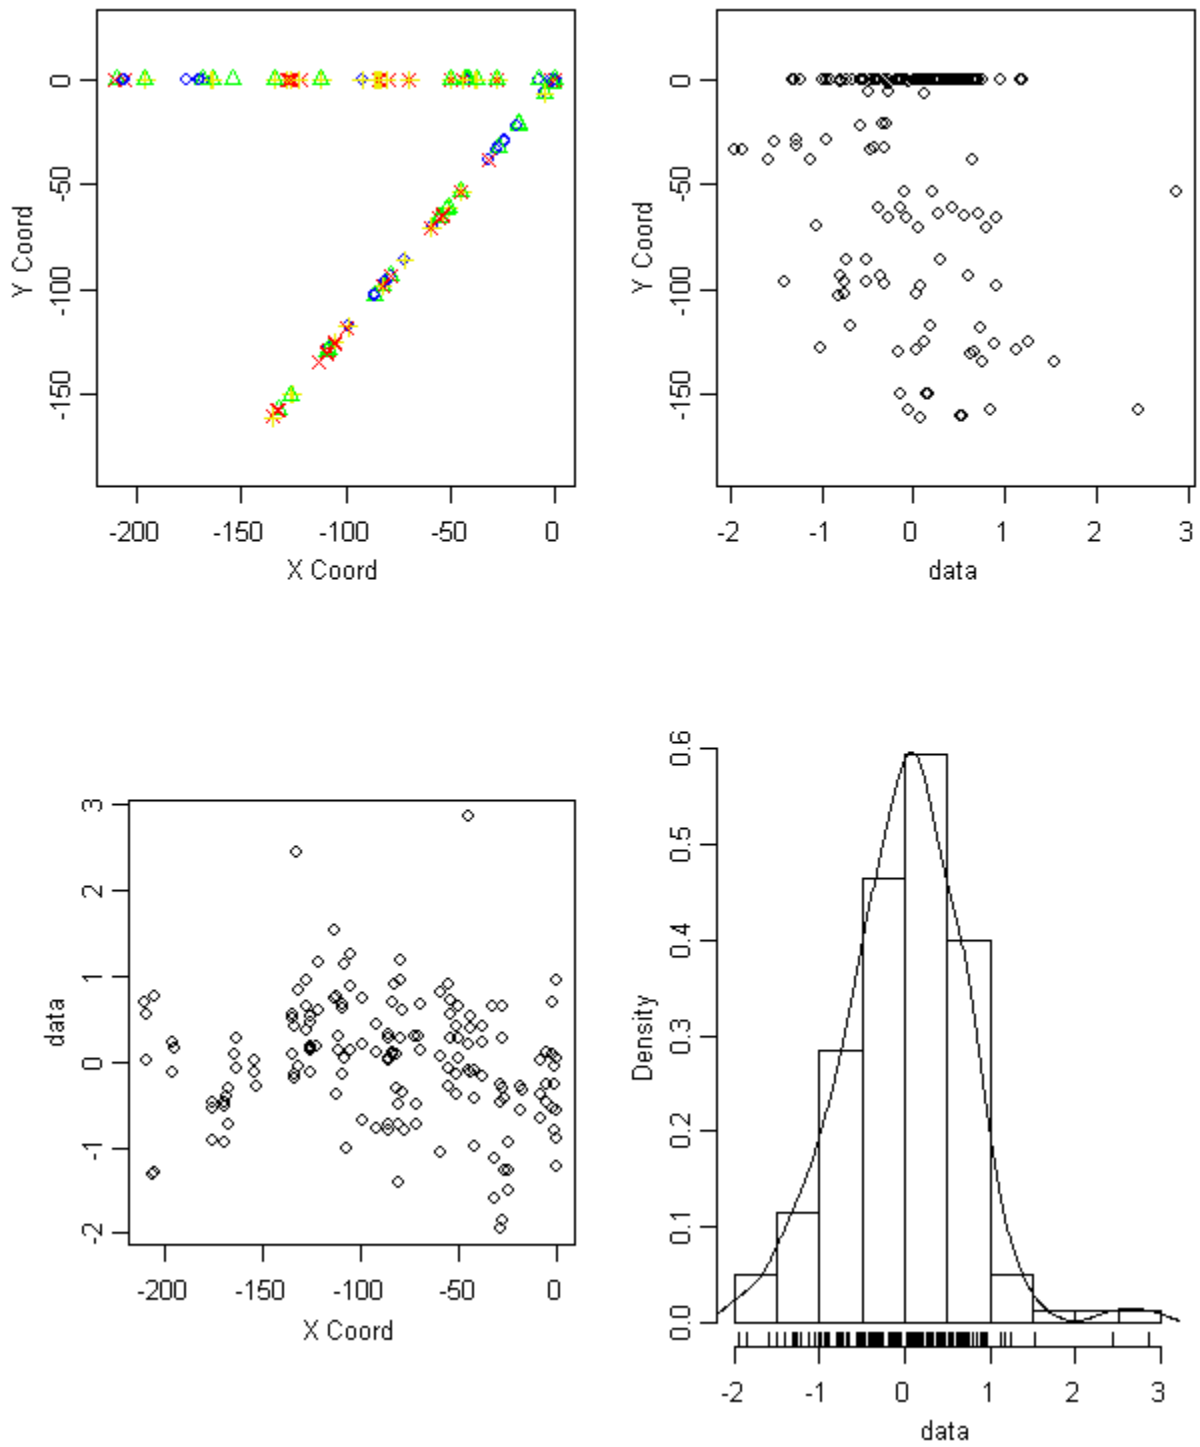

#### 4.2.4 Results and interpretation

##### ***Temperature***

The temperature data display a strong pattern as a function of time. A linear regression ( $p < 0.001$ ) of temperature on time was fit and used to extract this trend (Figure 29). Exploratory data analysis plots show that there is no distinct patterning of the residuals (Figure 30). Directional variograms of the residuals do not show any indication of anisotropy (Figure 31); however, there is an indication that the directional variograms may not be fully characterized as a consequence of the spatial layout of the sampling. A spherical covariance model was fit using Cressie weights (Figure 32) and the estimated distance of effective independence was 51 meters based on the temperature data. This information will be used to refine the design applied to the subsequent sites.

### **Soil Water Content**

The soil water content (SWC) data display a weak pattern as a function of time. A linear regression ( $p = 0.05$ ) of temperature on time was fit and used to extract this trend (Figure 33). Exploratory data analysis plots show that there is an increase in the spread of the residuals from left to right (lower left corner Figure 34). There are more samples collected in the right hand side of the plot, which would allow for more complete characterization of the underlying variability; however, these samples are also closer together which would tend to suggest more similar values in the presence of non-trivial spatial correlation. Directional variograms of the residuals do not show any indication of anisotropy (Figure 35); however, there is an indication that the directional variograms may not be fully characterized as a consequence of the spatial layout of the sampling. In addition, the directional variograms seem to suggest that the SWC data are relatively independent. A spherical covariance model was fit using Cressie weights (Figure 36) and the estimated distance of effective independence was 8 meters. This information will be used to refine the design applied to the subsequent sites.

#### 4.2.5 Summary

The estimated distance of effective independence was found to be 8 meters on SWC and the SWC pattern show relatively independent on the distance. The estimated distance of effective independence was 50 meters based on geospatial analysis of temperature data alone, which is impossible to separate soil plots so far apart due to the practical economic reasons. If we choose the distance of 40 meters for soil plots separation, we are still have 80% confidence that our measurements in soil are independent based on the temperature variograms (assume the relationship is linear below the distance of 50 meters in Figure 32), and this is as far as the financial support allows. Therefore, the recommended distance between soil plots is 40 meters at North Sterling relocatable tower site to best avoid the autocorrelation as our financial support permits.

### 4.3 Airshed

#### 4.3.1 Seasonal windroses

Wind roses analytically determine and graphically represent the frequencies of wind direction and wind speed over a given timeseries. The orientation of the wind rose follows that of a compass. When we describe the wind directions it should be noted that they are the cardinal direction that wind blows from. Color bands depict the range of wind speeds. The directions of the rose with the longest spoke show wind directions with the largest frequency. These wind roses are subdivided into as 24 cardinal directions.

Data used here are hourly from 2006 to July 2009. Data was obtained from the Colorado Agricultural Meteorological Network (COAGMET) [http://ccc.atmos.colostate.edu/~coagmet/rawdata\\_docs.php](http://ccc.atmos.colostate.edu/~coagmet/rawdata_docs.php). Data were collected by a propeller anemometer mounted at 2.2 m inside the CSU experimental area surrounded by no-till corn. Hence, the anemometer was below canopy height when corn reached its full, seasonal height. These data were collected approximately 40 m north-east from the proposed tower site. It is assumed that the wind data was corrected for declination.

#### 4.3.2 Resultant vectors

**Table 7.** The resultant wind vectors from North Sterling using hourly data from 2006 to 2009.

| Quarterly (seasonal) timeperiod | Resultant vector | % duration |
|---------------------------------|------------------|------------|
| January to March                | 24°              | 20         |
| April to June                   | 350°             | 18         |
| July to September               | 341°             | 21         |
| October to December             | 355°             | 14         |
| Annual mean                     | 357.5°           | na.        |

|   |                      |                  |

**Table 8.** The percent duration of winds among cardinal directions, 3 frequency bins on each side of the cardinal direction.

Data are from North Sterling using hourly data from 2006 to 2009. . Blue text and underline indicates the dominant, winds occurring for the cardinal direction >40% of the time.

| Quarterly (seasonal) timeperiod | Cardinal direction |      |       |      |
|---------------------------------|--------------------|------|-------|------|
|                                 | North              | East | South | West |
| January to March                | 30.7               | 24.0 | 22.5  | 22.3 |
| April to June                   | 36.5               | 16.8 | 21.7  | 20.4 |
| July to September               | <u>41.8</u>        | 10.6 | 24.6  | 19.6 |
| October to December             | 30.0               | 22.6 | 23.6  | 23.8 |

### 4.3.3 Acceptance criteria

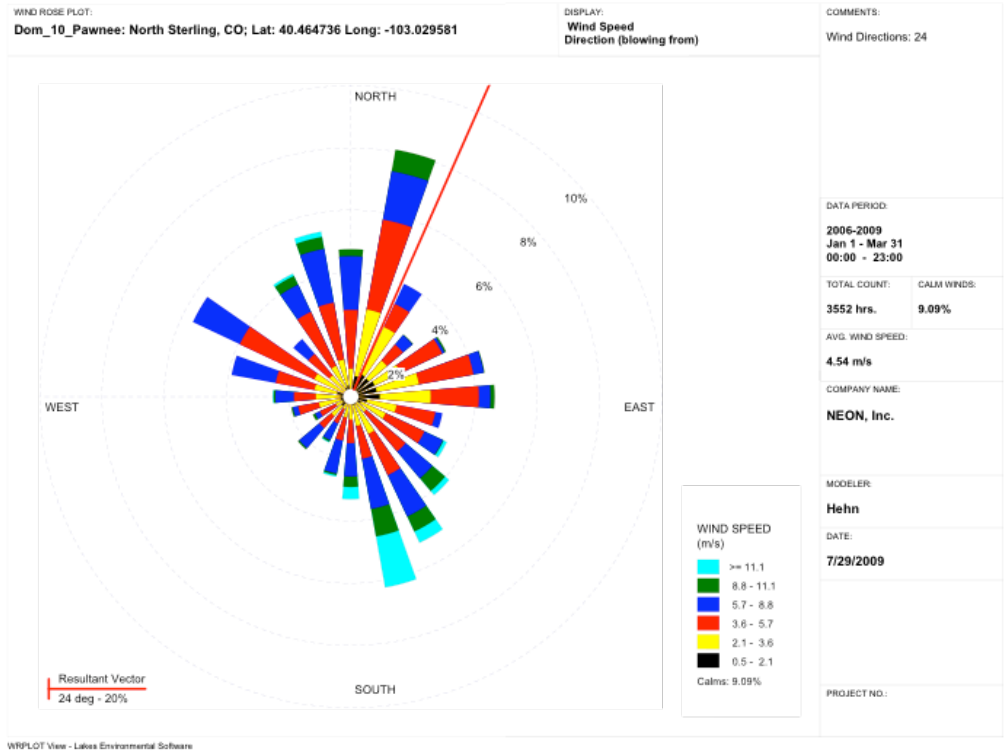

Winds are only dominant from the north quadrant (Table 8) during July-September, and annual resultant wind vector is from 358°. Winds come from the other quadrants during all other seasons. Convective fronts develop daytime winds along the front range and generally pass over the site, travelling from the west to the east, particularly during the spring and fall seasons. But as they pass over they re-direct the winds to other vectors, from the east, south etc. (Figure 37-40).

The desired measurements are from the surrounding agronomic field and contingent on annual economic decisions made by the land owner (shifting agriculture), with the co-dominant soil associations; Platner loam 3-5% slopes and Weld loam 1-3% slopes. Here, the parameters to estimate the tower footprint assume to be the most structurally complex agronomic decision--corn. The available west-to-east length of this ecosystem is ~800 m. Immediately to the east is a long term experimental field of no-till corn, managed by CSU. When wind comes from east, data would have to be inspected, which would be potentially biased by the differences between the CSU no-till corn and local management of the owners cropping. Regardless, the differences between these two cropping schemes will influence the microclimate and biochemical cycling (flux rates). Hence, flows from the east are least desirable. Because flows through the tower have to be examined and potentially removed from the dataset, placing the leeward side of the tower closest to the east (closest to the CSU plots), optimizes flows over the source area from the west. To maximize the fetch (source area) from the NW from the winter, spring and fall seasons, the tower location should be placed in the SE area of the parcel. Because winds from the south occur during the summer and the results from the footprint analyses (Figures 43, 44) indicate 80% of the cumulative flux is derived over ~ 200-300 m under summer convective conditions, the tower placement should be ~ 300 m north of the southern boundary. Instrument hut shall be placed in the leeward side of the tower and not influence the flows around the tower, hence, the distance of ~ 5 x the hut height towards the east of the tower is required (AD[02]).

**Figure 44.** Tower flux footprint output for North Sterling Relocatable site under convective conditions at maximum expected wind speed using an inverted plume dispersion model by Horst & Well.

Because the ecosystem has a height of the mean plant canopy 0-4 m, the Tower has been sited to i) optimize the temporal coverage of flow-based measurements over the representative environment, ii) minimize flow distortions caused by local ecosystem structure or topography (orography), and iii) allow the sensors on the tower booms to measure the representative surrounding environment. The location identified here and its final placement (e.g., construction activities, FCC micrositing) will have to be evaluated against these conditions and requirements.

To avoid edge effect on science measurements, tower, soil array, and sensor locations have been sited such that the meteorological sensors and soil sensors are  $\geq 60$  m away from the edge of the representative ecosystem in interest (crop ecosystem), and flux sensors are  $\geq 180$  m from the edge of the representative ecosystem. The sensor locations identified here and its (final) placement (e.g., during reviews, construction activities, FCC micrositing) will have to be evaluated against these conditions and requirements.

#### 4.3.7 Constraints on the FSU ecosystem plot locations

Winds are only dominant from the north quadrant (Table 8) during July-September, and annual resultant wind vector is from 358°. Winds come from the other quadrants during all other seasons. Convective fronts develop daytime winds along the front range and generally pass over the site, travelling from the west to the east, particularly during the spring and fall seasons. But as they pass over they re-direct the winds to other vectors, from the east, south etc. (Figure 37-40).

The ecosystem productivity plots should be placed within i) the overall, annual extent of the footprint, ii) within the bounds of the permitted property, iii) span the dominant and co-dominant soil types, and iv) estimate the productivity from the ecosystem if interest.

Given these constraint and the location of the tower, the shape of the overall, annual source is a large fan (where the apex is the tower location). The northern vector is  $358^\circ + 27^\circ = 25^\circ$ . But the western boundary of the CSU plots constrain the northern vector. The length of the northern vector is 400 m. The southern vector is  $135^\circ$  constrained by windrose and property boundary. The length of the southern vector is  $\sim 300$  m.

#### 4.4 Exclusion Zone

To meet our Product Assurance metrics, our high quality Terrestrial Instrument System (TIS) measurements, and TIS requirements, no sampling, observations, or experiment shall be conducted within the tower exclusion zone without consulting and resolving any issues with TIS scientists as according to the 'NEON Research Collaboration Document' NEON.DOC.004312. The intent is to limit any activities that can either affect the wind flows (e.g., disturbance, buildings, structures, clear cutting, affect changes in structure), or the natural/expected process rates. Because we cannot think of all such future activities, each will have to be evaluated on a case-by-case basis.

The exclusion zone is an area with these features:

- e) The shape of the exclusion zone appears as a pie splice (plan view) with center point of the tower foundation (plan view) as its origin.
- f) There may be more than one exclusion zone per tower, depending on the diurnal, seasonal and annual wind patterns.
- g) The exclusion zone is a sub-area (i.e., inside) the total tower source area
- h) Windrose analyses determine the wind vectors that bound the outside of the exclusion zone, which is clockwise from 135 to 25 degrees at this site (major).

There are two criteria to determine the distance of the exclusion zone from the tower:

- 3) For all activities mentioned above, the distance from the tower is the maximum value of 90% cumulative flux of the source area at mean maximum wind speed under daytime convective (expected unstable) atmospheres, which is 600 m at this site.
- 4) Some large disturbance activities also cannot occur in the nighttime tower footprint (because the nighttime tower footprint extends out much farther than the daytime

source area). For all high impact activities, the distance from the tower is the maximum value of 80% cumulative flux of the source area at mean maximum wind speed under nighttime, thermally stratified, (expected) stable atmospheric conditions, which is 790 m at this site.

## 5 CASTNET, RELOCATEABLE TOWER 2

### 5.1 Site description

The Rocky Mountain National Park Clean Air Status and Trends Network (RMNP CastNet) Relocatable tower site is located within the boundaries of RMNP at latitude N 40.27791° and longitude W 105.54584°. Current tower stake is at a relative flat clearing, which is surrounding by the heavily wooded mountain terrain, except some residential housing, clearing openings and some entertainment areas on the north-west direction. This direction is happen to be the prevailing direction, which means, if current tower location is used to set up tower, our measurements will be heavily impacted by human's daily activity instead of the natural mountain forest ecosystem that we are interested in. Plus, the recirculation at the edge of the forest would be another big concern for our turbulent measurements. Therefore, to solve this source area problem and the edge effect issue, tower location is suggested to be moved ~200 m toward south-west direction into a ponderosa pine wood stand at latitude N 40.27587° and longitude W 105.54629°.

The elevation for the tower site is at ~2750 m, on the western side of the Long's Peak (4346 m). The air drainage during the nights along the large and extended mountain slope could be a concern for the accurate turbulence measurements, as well as the CO<sub>2</sub> profile measurements on the forest ecosystem that we are interested in. The meteorological conditions in different seasons in 2006 are resented in Table 10, 11, and 12 (Barna et al., 2009).

**Table 10.** Summary statistics for core site hourly meteorological data during April 2006.

### 5.1.1 Ecosystem

Immediate to the suggested tower location, the vegetation are dominant by Ponderosa Pine forest (Figure 45), which typically distribute ~ 1680 m - 2850 m at RMNP. Mature trees large, with open rounded or flat-topped crown. Tree height can reach ~35 m, trunk massive, to ~1 m diameter. Bark is thick, reddish, with vanilla, or butterscotch scent. Needles are ~3 in to 7 in long, in bundles of 2 to 3. Female cones are large, woody, with a short spine on each scale. Trees scattered or in clumps, generally not crowded. Ponderosa pine forests are normally with diverse understory, dominated by shrubs and grasses (information source: <http://www.nps.gov/romo/naturescience/trees.htm>). However, the sources that contribute to the FIU measurements on the tower could include the signals from other ecosystem at higher altitude, *e.g.*, Douglas Fir, Lodgepole Pine, Rocky Mountain Juniper or Red Cedar, Quaking Aspen, etc. ((information source: <http://www.nps.gov/romo/naturescience/trees.htm>).

**Figure 45.** RMNP CastNet site is dominant by an open Ponderosa pine forest at the proposed new tower site.

|   |                      |                  |
|---|----------------------|------------------|
| Title: D10 FIU Site Characterization: supporting data | Author: Loescher/Luo | Date: 05/15/2013 |
| NEON Doc. #: NEON.DOC.011026                          |                      | Revision: D      |

Investigation at field indicates that the canopy height of the Ponderosa Pine forest ranged from ~20 m to ~27 m with a mean height of ~22 m near the suggested tower location. The roughness length ranges from ~1.5 m to ~2 m with a mean of ~1.8 m. The zero plane displacement height varies from ~ 16 m to ~23 m with a mean of ~20 m. Understory is dominant by shrubs and grasses shorter than 1 m. The average height for understory is ~ 20 cm.

## 5.2 Soils

Soil data and soil maps (Figure 46) below for RMNP CastNet Relocatable site were collected from 1 km<sup>2</sup> NRCS soil maps, which centered at the tower location, to determine the dominant soil types in the larger tower foot print. This was done to assure that the soil array is in the dominant (or in the co-dominant) soil type present in the tower footprint.

**Figure 46.** 1km<sup>2</sup> soil map for RMNP CastNet Relocatable site, center at tower location.

### 5.2.1 Description of soils

**Map Unit Description** The map units delineated on the detailed soil maps in a soil survey represent the soils or miscellaneous areas in the survey area. The map unit descriptions in this report, along with the maps, can be used to determine the composition and properties of a unit. A map unit delineation on a soil map represents an area dominated by one or more major kinds of soil or miscellaneous areas. A map unit is identified and named according to the taxonomic classification of the dominant soils. Within a taxonomic class there are precisely defined limits for the properties of the soils. On the landscape, however, the soils are natural phenomena, and they have the characteristic variability of all natural phenomena. Thus, the range of some observed properties may extend beyond the limits defined for a

|   |                      |                  |
|---|----------------------|------------------|
| Title: D10 FIU Site Characterization: supporting data | Author: Loescher/Luo | Date: 05/15/2013 |
| NEON Doc. #: NEON.DOC.011026                          |                      | Revision: D      |

taxonomic class. Areas of soils of a single taxonomic class rarely, if ever, can be mapped without including areas of other taxonomic classes. Consequently, every map unit is made up of the soils or miscellaneous areas for which it is named and some minor components that belong to taxonomic classes other than those of the major soils. Most minor soils have properties similar to those of the dominant soil or soils in the map unit, and thus they do not affect use and management. These are called non-contrasting, or similar, components. They may or may not be mentioned in a particular map unit description. Other minor components, however, have properties and behavioral characteristics divergent enough to affect use or to require different management. These are called contrasting, or dissimilar, components. They generally are in small areas and could not be mapped separately because of the scale used. Some small areas of strongly contrasting soils or miscellaneous areas are identified by a special symbol on the maps. If included in the database for a given area, the contrasting minor components are identified in the map unit descriptions along with some characteristics of each. A few areas of minor components may not have been observed, and consequently they are not mentioned in the descriptions, especially where the pattern was so complex that it was impractical to make enough observations to identify all the soils and miscellaneous areas on the landscape. The presence of minor components in a map unit in no way diminishes the usefulness or accuracy of the data. The objective of mapping is not to delineate pure taxonomic classes but rather to separate the landscape into landforms or landform segments that have similar use and management requirements. The delineation of such segments on the map provides sufficient information for the development of resource plans. If intensive use of small areas is planned, however, onsite investigation is needed to define and locate the soils and miscellaneous areas. An identifying symbol precedes the map unit name in the map unit descriptions. Each description includes general facts about the unit and gives important soil properties and qualities. Map Unit Description: Catamount gravelly coarse sandy loam, 5 to 20 percent slopes—Rocky Mountain National Park, Colorado, Parts of Boulder, Grand, and Larimer Counties Castnet\_1km Natural Resources Conservation Service Web Soil Survey National Cooperative Soil Survey 7/22/2009.

Soils that have profiles that are almost alike make up a soil series. All the soils of a series have major horizons that are similar in composition, thickness, and arrangement. Soils of a given series can differ in texture of the surface layer, slope, stoniness, salinity, degree of erosion, and other characteristics that affect their use. On the basis of such differences, a soil series is divided into soil phases. Most of the areas shown on the detailed soil maps are phases of soil series. The name of a soil phase commonly indicates a feature that affects use or management. For example, Alpha silt loam, 0 to 2 percent slopes, is a phase of the Alpha series. Some map units are made up of two or more major soils or miscellaneous areas. These map units are complexes, associations, or undifferentiated groups. A complex consists of two or more soils or miscellaneous areas in such an intricate pattern or in such small areas that they cannot be shown separately on the maps. The pattern and proportion of the soils or miscellaneous areas are somewhat similar in all areas. Alpha-Beta complex, 0 to 6 percent slopes, is an example. An association is made up of two or more geographically associated soils or miscellaneous areas that are shown as one unit on the maps. Because of present or anticipated uses of the map units in the survey area, it was not considered practical or necessary to map the soils or miscellaneous areas separately. The pattern and relative proportion of the soils or miscellaneous areas are somewhat similar. Alpha-Beta association, 0 to 2 percent slopes, is an example. An undifferentiated group is made up of two or more soils or miscellaneous areas that could be mapped individually but are mapped as one unit because similar interpretations can be made for use and management. The pattern and proportion of the soils or miscellaneous areas in a mapped area are not uniform. An area can be made up of only one of the major soils or miscellaneous areas, or it can be made up of all of them. Alpha and Beta soils, 0 to 2

percent slopes, is an example. Some surveys include miscellaneous areas. Such areas have little or no soil material and support little or no vegetation. Rock outcrop is an example. Additional information about the map units described in this report is available in other soil reports, which give properties of the soils and the limitations, capabilities, and potentials for many uses. Also, the narratives that accompany the soil reports define some of the properties included in the map unit descriptions.

### 5.2.2 Soil Semi-variograms

The goal of this site characterization of soil using semi-variograms is to determine the minimum distance between the soil plots in the soil array that can be considered spatially independent. The spatial variation of surface soil will be estimated using field sampling data of soil temperature and soil water content (SWC) in the tower airshed at Rocky Mountain National Park Clean Air Status and Trends Network (RMNP CastNet) Relocatable site.

The collected soil temperature and SWC data at field will be used for semi-variograms, which is a geostatistical technique to detect spatial autocorrelation between mapped samples of a quantitative variable (e.g. temperature and SWC in our case). In a variogram, the averaged squared difference in the residual value of a variable between all pairs of points is computed across distance intervals (lag classes). The output is presented graphically as a plot of the average semi-variance versus distance class (Figure 3). The semi-variance will converge on total variance at distances for which values are no longer spatially auto-correlated (this is referred to as the range, Figure 3).

|---|----------------------|------------------|
| Title: D10 FIU Site Characterization: supporting data | Author: Loescher/Luo | Date: 05/15/2013 |
| NEON Doc. #: NEON.DOC.011026                          |                      | Revision: D      |

Three parameters estimated from the variogram describe spatial autocorrelation in the data (Figure 3): the range, the sill (the sill is the asymptotic value of semi-variance at the range), and the nugget variance (which describes sampling error or variation at distances below those separating the closest pairs of samples). The range, sill and nugget variance were estimated from theoretical models that were fitted to the empirical variograms using non-linear least squares methods. The range distance (i.e. the distance beyond which samples are spatially independent) was estimated from the empirical variogram by fitting spherical theoretical models. This is the distance we will use to determine the spatial separation of soil plots in soil array.

The variogram analysis will be used in turn, to determine the spatial scales at which we can consider soil measurements spatially independent. This characterization will directly inform the minimal distance between *i*) soil plot within each soil array, *ii*) the soil profile measurements, *iii*) EP plots, and *iv*) the microbial sampling. These data will directly inform NEON construction and site design activities.

### 5.2.3 Soil Semi-variogram Method, experimental design, data analysis

Measurements of soil temperature and soil water content (SWC) were taken on August 13 and August 14, 2009 at the RMNP CastNet Relocatable tower site following the spatially cyclic sampling design by Bond-Lamberty et al. (2006, Figure 4). This design uses repeated pattern of samples to provide information about all distance with minimum of redundancy.

Because the current tower location (Latitude: N40.27791°, Longitude: W105.54584°) doesn't meet FIU science requirement about tower fetch in representative ecosystem. An alternative tower location is suggested at (Latitude: N40.27587°, Longitude: W105.54629°). The soil temperature and SWC measurements were conducted next to the suggested new tower location (Figure 47). Four 84-meter transects were established at RMNP CastNet Relocatable tower site (Figure 47, Figure 48). They were centered at a same point (Latitude: N40.27598°, Longitude: W105.54581°). 11 sampling points were taken along each transect. A Garmin GPS device was used to record the sampling location. The direction (compass magnetic degrees) for these 4 transects are 335°-155°, 290°-110°, 245°-65°, and 200°-20°, respectively.

3 replicates (30 cm apart from one another, Figure 49) were measured at each sampling point at fixed-depth (0-20 cm) using platinum resistance temperature sensors (Omega RTD810) for soil temperature and time domain dielectric sensors (CS616) for SWC at each sampling points. Data collected were used for geospatial analyses of variograms in the R statistical computing language with the geoR package to test for spatial autocorrelation (Goovaerts 1997, Trangmar et al. 1985, Webster 1989) and to determine the distance for soil plots in the soil array.

For all data sets for temperature and SWC, there is evidence for the existence of spatial trends that can be modeled as a function of time. This is a consequence of the fluctuating solar radiation throughout the day. Trends were estimated and removed with a simple two parameter linear regression model and p-values for the model significance are provided in the respective text below in results session. For the most part, this approach was sufficient with respect to satisfying the assumption of stationarity. Hence, variogram models were constructed on the residuals from these regressions of the response variable on time. The range distance (i.e. the distance beyond which samples are spatially independent) was estimated from the empirical variogram by fitting spherical theoretical models to both soil temperature and SWC data.

## 5.2.4 Results and interpretation

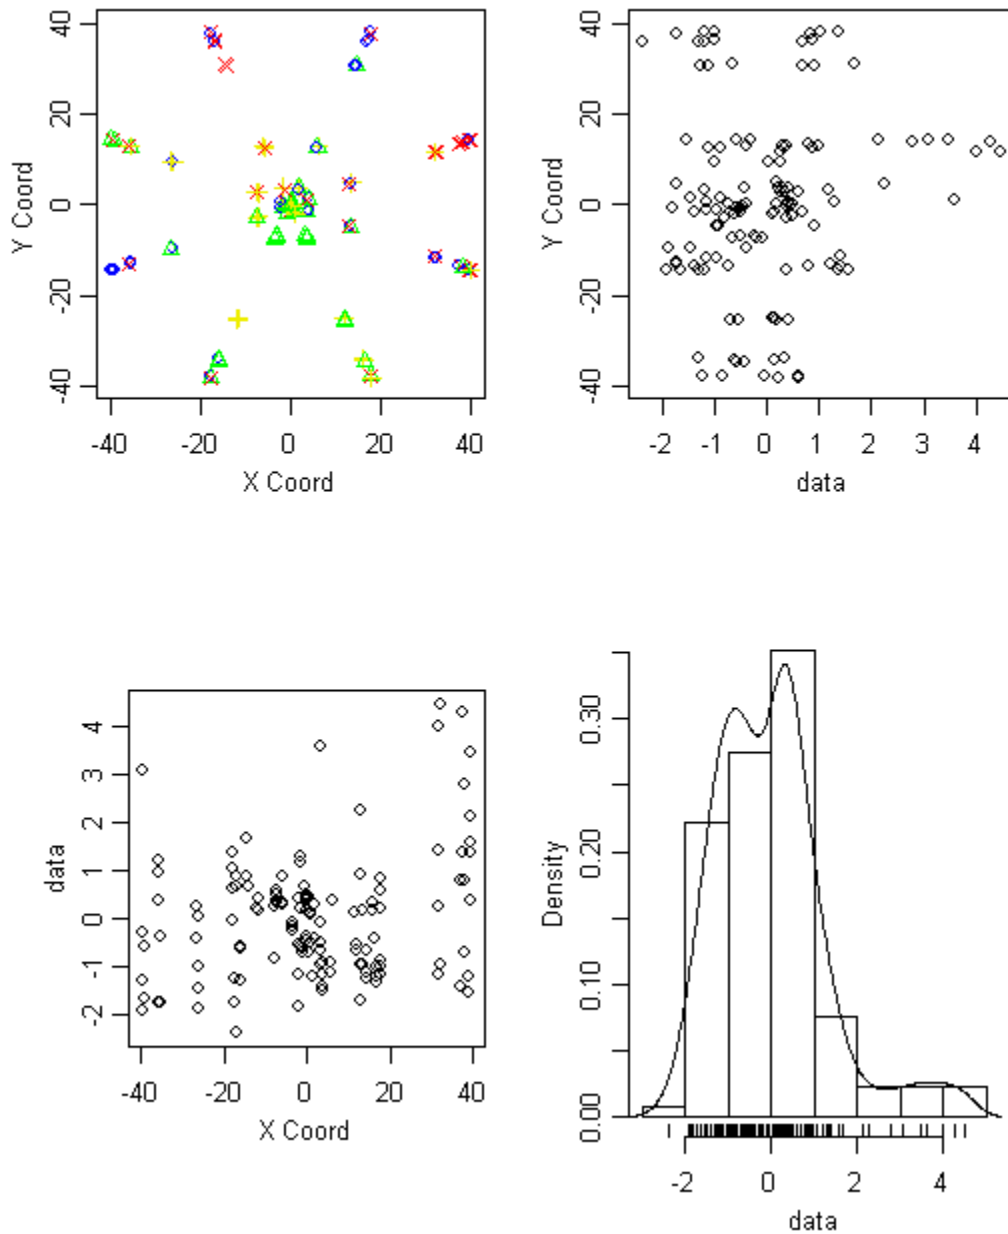

### *Temperature*

The temperature data display a strong pattern as a function of time. A linear regression ( $p < 0.001$ ) of temperature on time was fit and used to extract this trend (Figure 50). Exploratory data analysis plots show that there is no distinct patterning of the residuals (Figure 51). Directional variograms of the residuals do not show any indication of anisotropy (Figure 52). A spherical covariance model was fit using Cressie weights and a maximum distance of 125 meters (Figure 53). The estimated distance of effective independence was 101 meters (Figure 53). This information will be used to refine the design applied to the subsequent sites. If the maximum distance between samples in the final sampling design is less than the distance of effective independence, then increased sampling density may be required to achieve a nominal sample size in the presence of correlated data.

**Figure 52.** Directional variograms for residuals from regression of temperature on time at the RMNP CastNet relocatable site.

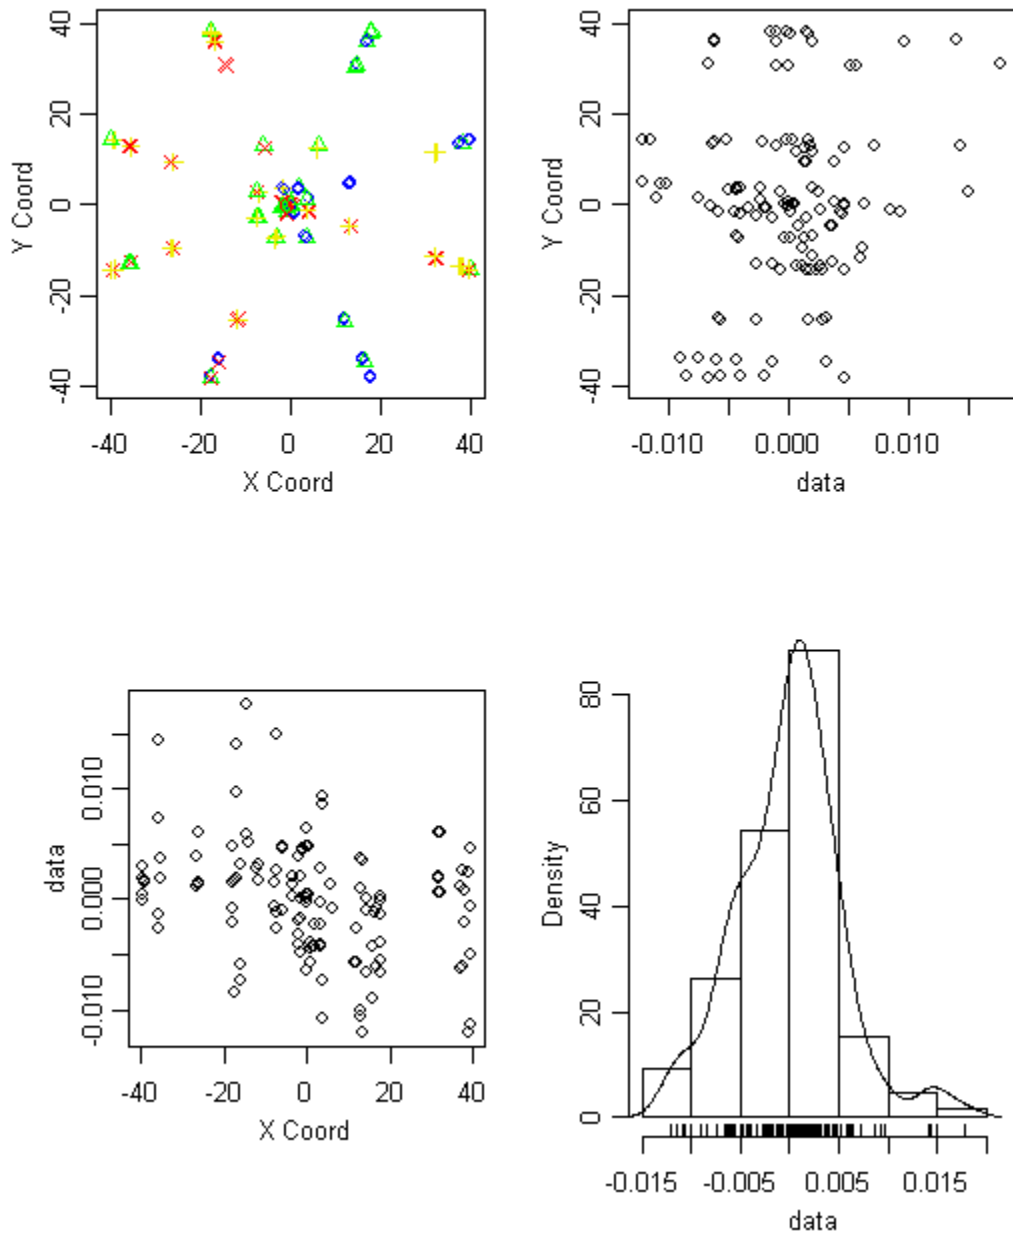

**Figure 53.** Empirical variogram and model fit for the residuals of the regression of temperature on time at the RMNP CastNet relocatable site.

### **Soil Water Content**

The soil water content (SWC) data display a weakly increasing pattern as a function of time. A linear regression ( $p = 0.03$ ) of temperature on time was fit and used to extract this trend (Figure 54). Exploratory data analysis plots show that there is a potentially decreasing trend from left to right across the horizontal extent of the data (lower left corner Figure 55). Directional variograms of the residuals do not show any indication of anisotropy (Figure 56). A spherical covariance model was fit using Cressie weights (Figure 57) and the estimated distance of effective independence was 35.0 meters. This information will be used to refine the design applied to the subsequent sites.

**Figure 54.** Time trend with linear regression fit and residuals for soil water content at the RMNP CastNet relocatable site.

**Figure 55.** Exploratory data analysis plots for residuals from regression of soil water content on time at the RMNP CastNet relocatable site.

**Figure 57.** Empirical variogram and model fit for the residuals of the regression of soil water content on time at the RMNP CastNet relocatable site.

### 5.2.5 Summary

The estimated distance of effective independence was 101 meters based on geospatial analysis of temperature data alone, which is impossible to separate soil plots so far apart due to the economic reasons. The temperature results should be discounted due to the non-uniform radiation heating on ground surface in the canopy opening areas. The estimated distance of effective independence was

found to be 35 meters with a well-defined sill based on the geospatial analysis on SWC. Therefore, the distance of 35 meters is recommended for the design of soil plots at the RMNP CastNet relocatable site.

### 5.3 Airshed

#### 5.3.1 Seasonal windroses

Wind roses analytically determine and graphically represent the frequencies of wind direction and wind speed over a given timeseries. The orientation of the wind rose follows that of a compass. When we describe the wind directions it should be noted that they are the cardinal direction that wind blows from. Color bands depict the range of wind speeds. The directions of the rose with the longest spoke show wind directions with the largest frequency. These wind roses are subdivided into as 24 cardinal directions.

Data used here are hourly data from 1999 to July 2009. Data was collected and obtained from the EPA CASTNET site, <http://www.epa.gov/CASTNET/sites/rom406.html>. Data were collected by a propeller anemometer mounted at 2.2 m inside the CASTNET experimental area in an open field surrounded by ponderosa pine (large edge effects). Hence, the anemometer was below canopy height and may be subject to large errors. These data were collected approximately 140 m from the proposed tower site. It is assumed that the wind data was corrected for declination.

#### 5.3.2 Resultant vectors

**Table 13.** The resultant wind vectors from CASTNET using hourly data from 1999 to 2009.

| Quarterly (seasonal) timeperiod | Resultant vector | % duration |
|---------------------------------|------------------|------------|
| January to March                | 306°             | 49         |
| April to June                   | 293°             | 33         |
| July to September               | 303°             | 36         |
| October to December             | 311°             | 50         |
| Annual mean                     | 303.3°           | na.        |

**Table 14.** The percent duration of winds among cardinal directions, 3 frequency bins on each side of the cardinal direction.

Data are from Castnet using hourly data from 1999 to 2009. Blue text and underline indicates the dominant, winds occurring for the cardinal direction >40% of the time.

| Quarterly (seasonal) timeperiod | Cardinal direction |      |       |             |
|---------------------------------|--------------------|------|-------|-------------|
|                                 | North              | East | South | West        |
| January to March                | 31.4               | 4.8  | 11.4  | <u>49.3</u> |
| April to June                   | 24.5               | 8.6  | 19.9  | <u>44.0</u> |
| July to September               | 24.5               | 9.8  | 14.8  | <u>44.7</u> |
| October to December             | 34.0               | 7.2  | 11.0  | <u>44.9</u> |

### 5.3.3 Acceptance criteria

Winds are dominant from the west quadrant across all seasons (Table 14), and annual resultant wind vector is from 303° (Table 13). However, the resultant vector is influenced by winds throughout the North and west over the continental divide. Daytime winds flow upslope contra to the predominant flows and often observed in mid-elevation sites throughout the front range. Overall, the winds are fairly constrained by direction, this is an advantage of this site.

The desired measurements are from natural ecosystems (in this case, Ponderosa Pine) mid-elevation of the western slope of the Rockies to assess dust and chemical transport. The source area of this site is complex with advective flows and large surface roughness from patchy ecosystem structure (forest, fields, rock outcrops, steep mountainous slopes, etc.). Co-located with this site is the CastNet atmospheric chemistry monitoring site in an open field. Tower placement should be avoided in the leeward side of an abrupt change in ecosystem structure (AD[01]). In other words, large wake effects and recirculation occur when wind flows over a tree canopy prior to flowing over a field (AD[01]). Hence, the tower placement should not be in the clearing field with the co-located CastNet monitoring.

The extent of the forest is patchy in this area. Residential areas (Salvation Army retreat, and ex-urban homes) are to the North and North-east of this parcel. To optimize measurement of the flows over the forest, i) the tower placement should be in align with the forest and the dominant wind flows, and ii) as far from the urban residences as possible. Placing the tower in the SW section of this parcel into the forest, not only achieves these criteria, but also allows for over-forest flows to occur upslope (from the daytime flows). Because wind velocities are often high, and summertime convective energy is lower than that found on the prairie, source areas are generally much larger than that found at the other D10 sites (section 5.3.6). Instrument hut shall be placed in the leeward side of the tower and not influence the flows around the tower, hence, the distance of ~ 5 x the hut height towards the east of the tower is required (AD[02]).

### 5.3.6 Results (source area graphs)

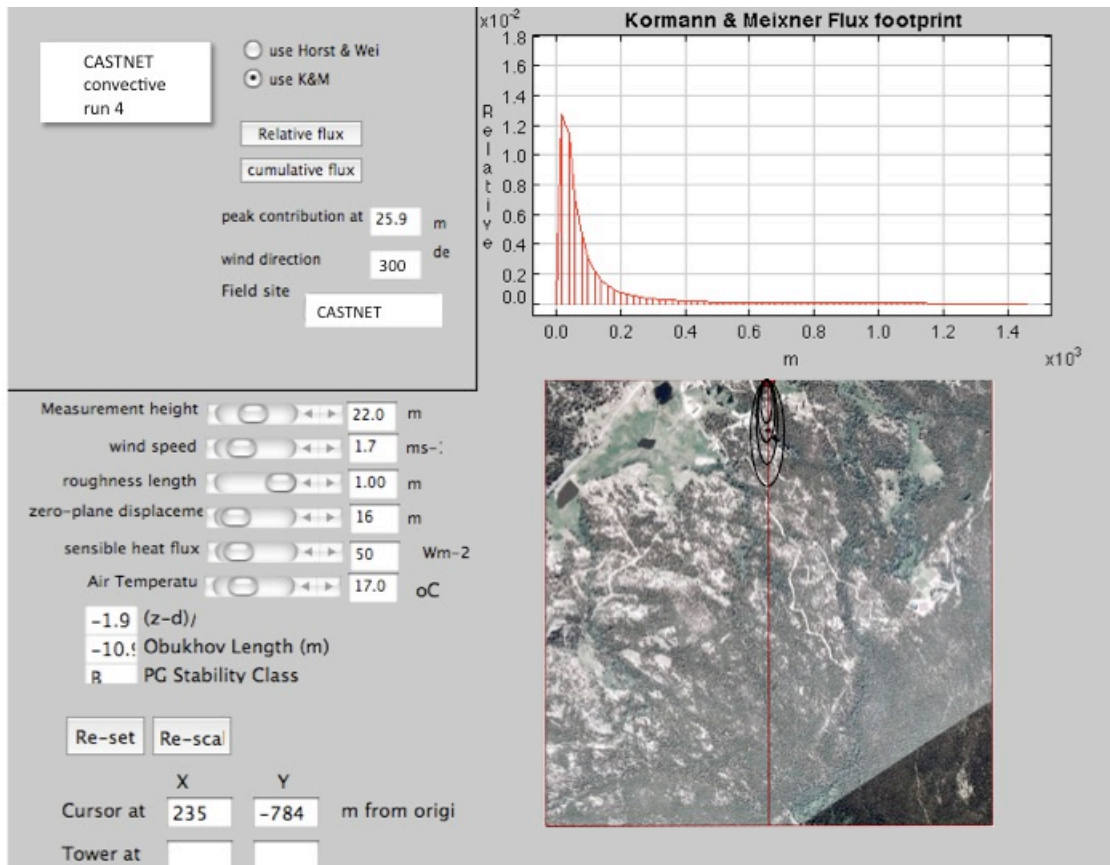

**Figure 62.** Tower flux footprint output for RMNP CastNet Relocatable site under near neutral conditions using an inverted plume dispersion model by Horst & Well.

**Figure 63.** Tower flux footprint output for RMNP CastNet Relocatable site under stable conditions using K&M model.

**Figure 64.** Tower flux footprint output for RMNP CastNet Relocatable site under convective conditions at maximum expected wind speed using K&M model.

**Figure 65.** Tower flux footprint output for RMNP CastNet Relocatable site under convective conditions at mean expected wind speed using K&M model.

Because the ecosystems has a height of the mean plant canopy > 1.75 m and the tower has to pass through the plant canopy vertically, tower has been sited to i) allow the tower pass through the canopy with minimizing the remove foliage during the tower establishment, ii) optimize the temporal coverage of flow-based measurements over the representative environment, iii) minimize flow distortions caused by local ecosystem structure or topography (orography), and iv) allow the sensors on the tower booms to measure the representative surrounding environment. The location identified here and its (final) placement (e.g., during reviews, construction activities, FCC micrositing) will have to be evaluated against these conditions and requirements.

To avoid edge effect on science measurements, tower, soil array, and sensor locations have been sited such that the meteorological sensors and soil sensors are  $\geq 60$  m away from the edge of the representative ecosystem in interest, and flux sensors are  $\geq 180$  m from the edge of the representative ecosystem. The sensor locations identified here and its (final) placement (e.g., during reviews, construction activities, FCC micrositing) will have to be evaluated against these conditions and requirements.

| NEON Doc. #: NEON.DOC.011026                          |                      | Revision: D      |

### 5.3.6.1 Constraints on the FSU ecosystem plot locations

Winds are dominant from the west quadrant across all seasons (Table 14), and annual resultant wind vector is from 303° (Table 13). However, the resultant vector is influenced by winds throughout the North and west over the continental divide. Daytime winds flow upslope contra to the predominant flows and often observed in mid-elevation sites throughout the front range. Overall, the winds are fairly constrained by direction, this is an advantage of this site.

The ecosystem productivity plots should be placed within i) the overall, annual extent of the footprint, ii) within the bounds of the permitted property, iii) span the dominant and co-dominant soil types, and iv) estimate the productivity from the ecosystem if interest.

However, property boundary does not allow for the size of ecosystem productivity plots. The available property in the dominant wind direction is also limited. This site does not desirable for the installation of ecosystem productivity plots.

## 5.4 Exclusion Zone

To meet our Product Assurance metrics, our high quality Terrestrial Instrument System (TIS) measurements, and TIS requirements, no sampling, observations, or experiment shall be conducted within the tower exclusion zone without consulting and resolving any issues with TIS scientists as according to the 'NEON Research Collaboration Document' NEON.DOC.004312. The intent is to limit any activities that can either affect the wind flows (e.g., disturbance, buildings, structures, clear cutting, affect changes in structure), or the natural/expected process rates. Because we cannot think of all such future activities, each will have to be evaluated on a case-by-case basis.

The exclusion zone is an area with these features:

- i) The shape of the exclusion zone appears as a pie splice (plan view) with center point of the tower foundation (plan view) as its origin.
- j) There may be more than one exclusion zone per tower, depending on the diurnal, seasonal and annual wind patterns.
- k) The exclusion zone is a sub-area (i.e., inside) the total tower source area
- l) Windrose analyses determine the wind vectors that bound the outside of the exclusion zone, which is clockwise from 263 to 341 degrees at this site (major).

There are two criteria to determine the distance of the exclusion zone from the tower:

- 5) For all activities mentioned above, the distance from the tower is the maximum value of 90% cumulative flux of the source area at mean maximum wind speed under daytime convective (expected unstable) atmospheres, which is 600 m at this site.
- 6) Some large disturbance activities also cannot occur in the nighttime tower footprint (because the nighttime tower footprint extends out much farther than the daytime source area). For all high impact activities, the distance from the tower is the

maximum value of 80% cumulative flux of the source area at mean maximum wind speed under nighttime, thermally stratified, (expected) stable atmospheric conditions, which is 1500 m at this site.
